**Biphenyl bridged hexadentate N6-ligands – a rigid ligand backbone for Fe(II) spin crossover complexes†**

Silvio Heider,a Holm Petzold,*a Guillaume Chastanet,b Stephan Schlamp,c Tobias Rüffer,a Birgit Weberc and Jean-François Létardb

The novel hexadentate nitrogen based ligand \( N,N'-\text{bis-(2-(1H-pyrazol-1-yl)pyridine-6-ylmethyl)-2,2'-biphenylenediamine} \) (3) was synthesized and used for the preparation of iron Spin Crossover (SCO) complexes \([\text{Fe}(3)][\text{BF}_4]^2 \) (4) and \([\text{Fe}(3)][\text{ClO}_4]^2 \) (5), which differ only by the respective counter ion. These complex salts show different spin transition temperatures \( T_{1/2} \) (135 and 157 K, respectively). This effect was studied by the investigation of the solid state structure of different low- and high-spin isomers. All complexes of this series show closely related crystal packing regardless of the counter ion, metal (Zn/Fe) and spin state. The isomer exhibiting the lower transition temperature (4) was also investigated in respect to its photomagnetic behaviour. The LIESST process could be monitored for this complex, but no reverse-LIESST was observed. The relaxation of the photo-induced state occurs at ca. 80 K, showing a complex, three-state relaxation mechanism.

**Introduction**

Spin Crossover (SCO) complexes have gained a huge interest, as they can change their spin state by external perturbation, e.g. change of temperature or pressure, light irradiation or guest molecules.1–8 The associated changes of color, magnetism, refractive index, etc. are promising for applications like displays, data storage or sensors.2,9–11 SCO complexes must contain a metal ion able to be present in its low-spin (LS) and its high-spin (HS) states. This is particularly the case for Fe(II) which in a suitable octahedral ligand field exhibits a diamagnetic (LS, \( S = 0 \)) ↔ paramagnetic (HS, \( S = 2 \)) crossover. The most appropriate ligand field is given by N6 coordination spheres leading to a suitable orbital splitting \( \Delta_O \) (10 Dq) for the observation of an equilibrium between the HS and LS states.3,5,12–19 In the high-spin form the anti-bonding \( e_g \) orbitals are filled with two electrons, while in the case of the low-spin form only the non-bonding \( t_{2g} \) orbitals are filled. Thus huge structural changes are observed along the SCO due to Fe–N bond length variations around 0.2 Å.20 Furthermore the high-spin isomers often expose large deviations from the octahedral geometry, while the corresponding low-spin isomers show less distorted \( O_6 \) coordination spheres.18,20–24

It has been shown that those great structural changes associated with a rigid ligand scaffold increase the lifetime of the photo-induced state reached by the LIESST phenomenon.6,19,25–27 This might be due to an increased activation energy for rotational vibration modes, as shown by Hendrickson et al.28 This is particularly visible on the evolution of \( T(T\text{LIESST}) \), the temperature above which the photo-induced state is erased, upon ligand denticity and rigidity.6,26 Therefore we are interested in covalently fixed hexadentate nitrogen ligands which are able to coordinate in an octahedral fashion, the covalent linking of nitrogen donors should lead to increasing distortions upon SCO. Only a few examples have been investigated in detail.29–35

Recently, we reported a facile synthesis of such ligands and of the obtained Fe(II) SCO complexes 7–9,36 which showed an interdependency of the SCO transition temperature and the substitution pattern in the backbone due to steric effects. Herein we want to report the electronic and structural modification of those complexes by replacing a pyridyl moiety with a 1H-pyrazol-1-yl fragment and the investigations of the resulting iron(II) SCO (4/5) complexes (Fig. 1).
Results and discussion

Synthesis

First of all 2-(1H-pyrazol-1-yl)pyridine-6-carbaldehyde was synthesized by an improved methodology compared to the existing ones (see the Experimental section). In this two-step process first 2,6-dibromopyridine and 1H-pyrazole give a mixture of di- and mono-substitution products, i.e., 2,6-di(1H-pyrazol-1-yl)pyridine and 2-bromo-6-(1H-pyrazol-1-yl)pyridine. Inspired by the previously published procedure for the synthesis of substituted bipyridines by Negishi cross coupling and the easily attempted purification of the appropriate low-soluble zinc complex, we tried a similar purification method for this reaction mixture.

Indeed successive addition of ZnCl₂(xH₂O) to the mixture of 2,6-di(1H-pyrazol-1-yl)pyridine and 2-bromo-6-(1H-pyrazol-1-yl)pyridine precipitates first the 2,6-di(1H-pyrazol-1-yl)pyridine complex and upon further addition of ZnCl₂(xH₂O) the desired 2-bromo-6-(1H-pyrazol-1-yl)pyridine complex. This selective formation allows the easy separation of both compounds by filtration or centrifugation. Adequate workup by treatment of the zinc complex with ammonium hydroxide or EDTA solution leads to the desired compound in 60% yield, with high purity and without any use of column chromatography. Therefore we assume that this method is less time and solvent consuming.

A reaction of bromopyridine in diethyl ether at ca. −80 °C with one equiv. of nBuLi followed by the addition of N,N-dimethylformamide (DMF) gave 2-(1H-pyrazol-1-yl)pyridine-6-carbaldehyde (2) quantitatively as a pale-yellow solid (Scheme 1).

The synthesis of compound 3 was accomplished in an analogous manner as previously described. Biphenylene-2,2'-diamine was converted with 2 equiv. of aldehyde 2 in EtOH to the corresponding Schiff base and then reduced in situ with NaBH₄ to give the secondary amine 3 in good yields and high purity (Experimental section). Subsequently, diamine 3 was reacted with 1 equiv. of [Fe(H₂O)₆][BF₄]₂, [Fe(H₂O)₆][ClO₄]₂ or [Zn(H₂O)₆][BF₄]₂ to give complexes [Fe(3)]-[BF₄]₂ (4), [Fe(3)][ClO₄]₂ (5) and [Zn(3)][BF₄]₂ (6), respectively, which were precipitated by addition of diethyl ether and thereafter yielded purely (Scheme 2).

Physical measurements

NMR spectroscopy. The ¹H NMR spectra of diamine 3 show the expected signals, i.e. the signals for the CH₂ and NH protons at 4.40 and 5.13 ppm, respectively, and in the range from 6.3–8.0 ppm the signals of the aromatic bonded protons appear. The same expected behaviour is found for the ¹³C[¹H] NMR, where one signal at 48.1 ppm represents the methylene group, whereas 14 signals in the region from 107–157 ppm match the structure of the aromatic part. In the case of the iron complexes 4 and 5 thirteen signals can be found in the ¹H NMR spectrum (Fig. 2), the CH₂ protons are diastereotopic.
due to the fixed arrangement of the biphenyl connectivity upon complexation. Also these signals are spread from ca. −70 to 75 ppm, which is common for paramagnetic complexes. Additionally, other small signals appear, which seem to belong to another paramagnetic complex. As the elemental analyses and mass spectra fit well to the desired complexes, this paramagnetic complex probably is another stereoisomer, because NMR spectra in d₆-acetonitrile also show those signals, although the solubility of the complex is low (ESI, Fig. S4†). However partial hydrolysis cannot be ruled out as origin of those signals.

Thus the complex [Fe(3)⁺⁺] is present in its high-spin configuration at room temperature, in contrast to the previously published complex 7, where the pyrazolyl fragment is substituted by a pyridine moiety (Fig. 1) and shows almost 100% low-spin character at room temperature. This is on the one hand attributable to the lower σ-donor- and π-acceptor-capabilities of pyrazol compared with pyridine; on the other hand in this ligand system the incorporation of the pyrazolyl moiety also leads to less favourable bond angles (vide infra). Nevertheless, the splitting of the CH₂ signals still indicates the C₂ symmetry and therefore proves the stability of the complexes with regard to ligand exchange and solvolysis in acetonitrile.

Magnetic properties

The magnetic behaviour of complex 4 was investigated in solution by Evans’ method in CD₃CN and (CD₃)₂CO (Fig. 3). Those data were fitted with the regular solution model (eqn (1)) resulting in T₁/₂ = 196 K, ΔH = 10.8 kJ mol⁻¹ and ΔS = 55 J K⁻¹ mol⁻¹.

\[
\mu_{\text{eff}} = \frac{5.0\mu_B}{1 + \exp \left( \frac{\Delta H}{R \left( \frac{1}{T} - \frac{1}{T_{1/2}} \right)} \right)}
\]  

The magnetic behaviour of polycrystalline samples of 4 and 5 were investigated by SQUID measurements from 300 K to 10 K under 0.2 T magnetic field (Fig. 4). At room temperature, the χₜₑₑₜ products (χₜₑₑ stands for the magnetic molar susceptibility) show typical values for HS Fe(II) complexes with χₜₑₑₜ = 3.6–4.1 cm³ K mol⁻¹. Upon cooling, a strong decrease down to χₜₑₑₜ = 0.2–0.3 cm³ K mol⁻¹ at T = 10 K is observed, typical for LS iron(II) complexes with small paramagnetic residues. A spin state crossover can be observed in both salts, one centered at 135 K in 4 (Fig. 3), which shows a narrow hysteresis of approximately 4 K (T₁/₂↓ ≈ 133 K, T₁/₂↑ ≈ 137 K), the other one centered at 157 K without showing a hysteresis in 5.

The population of the high-spin metastable state at low temperature was accessible by fast cooling of the sample from room temperature to 10 K. Then, the sample is warmed at the 0.3 K min⁻¹ scan rate in order to record a T(TIESST) temperature (TIESST stands for Thermally-Induced Excited Spin-State Trapping). Fig. 5 reports this T(TIESST) curve for compound 4 in comparison with the thermal Spin Crossover...
From 10 K to 50 K the small increase of $\chi M T$ reflects the presence of zero-field splitting of the paramagnetic HS state. The maximum $\chi M T$ value reached at $\approx 50$ K gives some information on the quench efficiency (40%). Above 50 K the high-spin $\rightarrow$ low-spin relaxation becomes efficient and the $\chi M T$ decreases to recover the low-spin ground state above 80 K.

From the derivative of the curve, the $T_{\text{TIESST}}$ value of 81 K can be extracted pointing out the position of the minimum (inset in Fig. 5, black curve). This curve will be particularly interesting compared with the one recorded after photo-excitation.

**Photomagnetic properties**

The photomagnetic properties of compound 4 have been investigated. The first step was to record the diffuse reflectance thermal behaviour (Fig. 6). At room temperature, the spectrum is mainly constituted by an MLCT band centered at 620 nm with several shoulders at 700 and 750 nm. Around 850 nm a weak band could be observed as a signature of the d–d absorption band of the high-spin isomer. Upon cooling to 100 K the MLCT band increases indicating the population of the low-spin state, in correlation with the decrease of the 850 nm band. The reflectivity signal followed at 620 nm (Fig. 6, inset on the left) indicates a thermal Spin Crossover around 140 K, in good agreement with the magnetic data (vide supra). Below 100 K, the reflectivity signal at 620 nm strongly increases in correlation with a decrease of the MLCT absorption band and an increase of the 850 nm band. The spectrum at 10 K is similar to the one at 280 K proving the population of the high-spin state according to the LIESST effect.

Then, susceptibility measurements were carried out on a thin layer of compound 4. Irradiation was tested at different wavelengths and the best conditions were found to be at 514 nm with a 1 mW cm$^{-2}$ power. Whatever the wavelength used (514, 647 and 830 nm), only the LIESST effect was observed and no reverse-LIESST. After the saturation is reached at 10 K, the $T_{\text{LIESST}}$ curve was recorded. Almost 90% of the low-spin molecules are photo-converted into the high-spin metastable phase. The $T_{\text{LIESST}}$ curve shape differs from the $T_{\text{TIESST}}$ one above 60 K with the occurrence of a two-step transition. The low temperature step appears to be quite gradual, spreading over almost 15 K while the high temperature step presents a sharp transition. The derivative of the $T_{\text{LIESST}}$ curve confirms these observations by the presence of two minima, one very large at 72 K, and one very steep at 82 K (inset in Fig. 5, green curve). A third minimum can even be observed at 80 K which is quite unusual.

Relaxation kinetics have been recorded to characterize the relaxation process of the photo-induced state (Fig. 7). The metastable high-spin state clearly relaxes following a multistep process as a reflect of the $T_{\text{LIESST}}$ curve. A first exponential relaxation occurs at short time and two very close relaxations take place at longer delay. At least one of these two last relaxations exhibits a cooperative behavior. The relaxation kinetics of the quickly cooled state have also been investigated (ESI,
Fig. S6). However those relaxation curves also present two relaxation rates since a first exponential behavior appears at short time and a sigmoidal one at longer times. Therefore, the extraction of the dynamical parameters becomes tricky in both the photo-induced and the quickly-cooled states.

**X-Ray crystallography**

The crystal structures of compounds 4 and 5 were investigated by temperature dependent powder and single-crystal X-ray diffraction. The temperature-dependent XRPD measurements for 4 (ESI, Fig. S12–S14†) show first that only one isomorph is present and no other phases with intermediate spin could be observed. Furthermore the same transition temperature as the one extracted from the magnetic characterization was found.

Crystals suitable for X-ray analysis were grown by diffusion of diethyl ether vapors into concentrated solutions of the complex salts 4, 5, and 6 in CH3CN. The crystallization affords reproducibly well shaped crystals of the complexes without incorporating packing solvents. Data were collected by X-ray diffraction on these crystals at different temperatures and then solved. At all temperatures the lattice of the crystals can be described in monoclinic space groups, P21/n (4 at 90 K, 5 and 6 at 110 K) and P21/c (4, 5 at 295 K).

At low temperature both iron salts as well as the zinc complex 6 show two independent molecules of the complex in the asymmetric unit, while at room temperature for both iron salts only one complex molecule (together with the corresponding anions in all cases) is present. Surprisingly, the corresponding zinc complex 6, which is a model for an iron(ii) high-spin complex, also shows two molecules in the asymmetric unit. This is in contrast to the iron(ii) high-spin structures that only show one molecule in the asymmetric unit. The unit cell dimensions of the iron complexes 4 and 5 in the low-spin and high-spin states are closely related as the space groups P21/n and P21/c are interchangeable. Moreover the unit cell of the iron complexes 4 and 5 in the high-spin state (P21/c) can be yielded to a good approximation by simply cutting the unit cell of complex 6 or 4 and 5, respectively, determined at low temperatures (P21/n). This is schematically explained in the ESI (Fig. S11†). In contrast to other systems the presence of two different sites for the iron complexes in the crystal lattice does not lead to a two-step transition, as otherwise often observed.51–54

A closer look at the crystal structure revealed only small differences in the atomic distances and angles between the two independent molecules in the low temperature structures; therefore we assume that the phase transition can be explained by the increasing thermal movement of the atoms at room temperature averaging the small structural differences of the independent molecules.

In compound 4 at 90 K Fe–N bond lengths from 1.8945(1)–2.063(2) Å are found, while in 5 the Fe–N bond lengths at 110 K account to 1.911(2)–2.069(3) Å representing a low-spin complex in both cases. At 295 K the Fe–N bond lengths in 4 take values between 2.102(2)–2.238(2) Å and for 5 2.118(4)–2.252(5) Å, showing a high-spin complex in both cases. This is in agreement with the SCO behavior discussed above.

As mentioned above, the T1/2 value for the SCO in the two iron complexes is different, thus we examined the packing and intra- and intermolecular contacts further, as it is known that hydrogen bonds and π–π stacking influence the SCO process and the cooperativity.10,55

In 4 H–F interactions between the NH groups of the ligand and the BF moieties of the counter cations exist, as well as H–O contacts in 5 between the NH amino groups and the perchlorate counter ions (see ESI, Fig. S10†). As can be seen in Table 1 in the low-spin configurations similar or slightly smaller hydrogen-X (X = O, F) bonds can be found compared to the respective high-spin structures. The differences found are relatively small. The longer contacts found in the high-spin structures in respect to the low-spin isomers may be simply attributed to the higher temperature of data collection, while the differences between BF4 and ClO4 salts originate from the different nature of hydrogen interaction to fluorine and oxygen, respectively. This is probably enough to explain the effect of changing T1/2 by about 20 K. For explaining the decreased T1/2 in contrast to the solution, one could assume that the host prefers the high-spin forms as the crystal lattice was originally formed by high-spin complexes at ambient temperature.

Both salts of [Fe(3)]2+ undergo a spin transition between 90 K and room temperature. This change of the spin state is not only accompanied by the elongation of the bond lengths

---

*The average value of the six Fe–N bond lengths. *b* The sum of the deviations from 60° of the hypothetical fac-trigonal planes against each other. *c* The sum of the deviations from 90° of the twelve cis-angles φ in the octahedral coordination sphere. *d* θ(8) – θ(7). *e* θ(9) – θ(7). *f* Σ(9) – Σ(7).
towards higher temperature, but also by a change of the N–Fe–N bond angles. In the low temperature structure those are nearer to an ideal octahedron than in the high-temperature phase. For the distortion in octahedral complexes several parameters were defined,\textsuperscript{18,19,28} of which \(\Sigma\) and \(\Theta\) shall be introduced and used for these examples. \(\Sigma\) is given by the sum of the deviations of the twelve \(\text{cis}\) N–Fe–N angles \(\varphi\) from 90° (eqn (2)), \(\Theta\) is calculated by the sum of the deviations of the \(\text{N–Fe–N}\) angles \(\theta\) between the projections of the triangular faces from 60° (eqn (3), Fig. 8).

\[
\Sigma = \sum_{i=1}^{12} |90° - \varphi_i| \tag{2}
\]

\[
\Theta = \sum_{j=1}^{24} |60° - \theta_j| \tag{3}
\]

\(\Sigma\) is proportional to the distortion from the octahedral geometry, while \(\Theta\) is more indicative of the special distortion towards a trigonal prismatic arrangement and also takes bond length alterations into account. For an ideal octahedron both values are zero, i.e. \(\Sigma = \Theta = 0\). For the complex salt \(4\) \(\Sigma_{\text{ls}} = 79.3°/80.3°\) and for the high-spin complex \(\Sigma_{\text{hs}} = 137.6°\), while for \(5\) \(\Sigma_{\text{ls}} = 77.2°/80°\) and \(\Sigma_{\text{hs}} = 137.4°\). Compared to other complexes, it becomes clear that Fe(II) SCO complexes with bidentate nitrogen donors show much smaller deviations, typically \(\Sigma_{\text{ls}} \approx 40°-60°\) and \(\Sigma_{\text{hs}} \approx 70°-85°\). This demonstrates the fixed structure of the hexadentate ligand system \(3\), which cannot adopt an ideal octahedral coordination sphere like it is possible with, for example, three bidentate ligands. Furthermore it can be seen that the difference of the deviation parameters, \(\Delta\Sigma\), which is approximately 30° for bidentate ligand based complexes,\textsuperscript{19} accounts to ca. 57°-60° for these hexadentate complexes. These values, \(\Sigma_{\text{ls}},\Sigma_{\text{hs}}\) and \(\Delta\Sigma\), are in quite good accordance with those for \(\text{[Fe(1-bpp)]}_{2}^{2+}\) (10) and a vast amount of similar 2,6-bispyrazolylpyridine iron(II) complexes, where typically \(\Sigma_{\text{ls}}\) lies in the range from 144°-158° and \(\Sigma_{\text{hs}}\) lies in the range from 80°-96°, resulting in \(\Delta\Sigma\) ranging between 54°-70°.\textsuperscript{18,19}

Compared to previously reported hexadentate low- and high-spin iron(II) complexes, \(7\) and \(9\), with ligands of similar structures, it can be seen that they show smaller values for \(\Sigma\), i.e. \(\Sigma_{\text{ls}} = 63.6°\) \((7)\) and \(\Sigma_{\text{hs}} = 128.7°\) \((9)\), showing a less distorted coordination geometry \((\text{vide infra})\). The difference between these two complexes, i.e. \(\Delta\Sigma = \Sigma(9) - \Sigma(7) = 65.1°\), is even a little larger than for the title compounds \(4\) and \(5\). Hence, it seems clear that the magnitude of structural change upon SCO for this type of iron(II) compound with this 2,2′-diaminobiphenyl N6 ligand system is in every case very large and comparable similar within this series, and also with iron(II) complexes with two tridentate bispyrazolylpyridine ligands on the other hand.

For \(\Delta\Theta\) it has been stated that this deviation parameter has much more influence on \(T_{1/2}\) and \(T(\text{LIESST})\) than \(\Delta\Sigma\).\textsuperscript{19} It is obvious that \(7\) and \(9\) show a similar, only slightly larger trigonal distortion than \(10\), with 192° and 185°, respectively. The respective title compounds \(4\) and \(5\) also show similar \(\Delta\Theta\) values, ranging from 169° to 186°. This means that the trigonal distortion upon SCO for \(4\) and \(5\) is comparable to that of \(\text{[Fe(1-bpp)]}_{2}^{2+}\) \((10)\). The expectation of a high \(T(\text{LIESST})\) value is not fully met by the found value of \(\approx 80\) K placing complex \(4\) on the \(T_{0} = 120\) K line.\textsuperscript{6,26} Interestingly, \(tren\) ligand based SCO complexes also lie on this \(T_{0}\) but they undergo a much smaller distortion of the coordination sphere.\textsuperscript{33} In contrast, both relaxation kinetics and magnetic measurements showed high cooperative behaviour in the solid state for complexes \(4\) and \(5\) reflected by the steep spin transition in both salts and the cooperative relaxation of compound \(4\) after excitation with light.

In order to find out more about the influence of the ligand on the structural changes we have calculated the elongation of the distances between adjacent nitrogen atoms in the coordination sphere upon SCO. Not surprisingly, these distances change to a greater extent for nitrogen atoms which are not directly connected by the ligand backbone. On average these seven \(N\cdots N\) distances differ by 0.41 Å in complex \(5\). Much smaller are the changes in the \(N\cdots N\) distances within the ligand backbone which are on average 0.12 Å smaller in the low-spin state. Apparently large with 0.25 Å is the difference for the distance \(N1\cdots N4\), the nitrogen atoms bound to the biphenyl bridge, due to the flexibility of the biphenyl moiety. Taking this into account, the average difference within the side arms \((N1\cdots N2\cdots N4\cdots N5\cdots N6\cdots N8)\) is much smaller with about 0.07 Å. Fig. 9 shows an overlay of the molecular structures of complex \(5\) in the respective low- and high-spin
states. Due to the fixed ligand backbone the differences between these spin states amplify at the end of the ligand arms, N4 and N8 are replaced by about 0.35 Å from their original positions upon Spin Crossover whereas N1 and N5 are displaced by only 0.2 Å. A rough picture from the molecular structure of the high-spin isomer can be extracted from the zinc complexes 6 and 11, where bond angles and distortion parameters are almost the same. Using the zinc complex as a model is therefore a good approach to evaluate structural changes in an SCO system if the high-spin structure is not available.

As mentioned above, the bond angles between the metal ion and the terminal pyrazolyl unit are not as ideal as in corresponding pyridine substituted derivatives (7, 9). In all cases, the donating atom is an aromatic nitrogen atom (Fig. 10). As the lone pair is located in an sp\(^2\) orbital in a six membered or five membered aromatic system, the ideal bond angle would be 120° and 126°, respectively. In Table 2 it can be seen that the spin state of the corresponding metal ion in the complex has minor influence on these angles. More important is the geometry of the heterocycle: the six membered terminal pyridine rings in 7 and 9 lead to only small deviations from 120°, moreover the difference between α and β is small (about 10°), while the five membered, more strained pyrazole rings in 4 and 5 lead to great deviations from the idealized angle, especially for β, which is in all cases slightly above 140°. Also the difference between α and β is much larger (about 30°).

Therefore, the pyrazolyl substituted ligands in 4/5 cannot donate as well to the metal ion as the pyridine substituted derivatives. The lone pair of the pyrazolyl nitrogen points somewhat away from the iron atom. This is one reason for the lower ligand field splitting induced by 3 in comparison to the pyridine derivative. Moreover the higher strain within the coordinated ligand results in a lower stability of the complexes 4/5 compared to 7/9.

## Conclusions

We have developed a new, straightforward two-step synthetic route to 2-(1H-pyrazol-1-yl)pyridine-6-carbaldehyde (2), which was then converted to the novel hexadentate secondary amine 3, possessing two amino-, two pyridine- and two pyrazolyl-donor functions. With this we synthesized a new Fe(n) SCO complex as two different salts, [Fe(3)[BF\(_4\)]_2 (4) and [Fe(3)][ClO\(_4\)]_2 (5), which show different spin transition temperatures depending on the counter ion, while in solution another different transition temperature is found for [Fe(3)]\(^{2+}\). By solution and investigation of the X-ray structures of these salts in their respective low-spin and high-spin forms this effect was attributed to different hydrogen bonding interactions between NH and ClO\(_4\)/BF\(_4\), respectively.

Furthermore photomagnetic measurements were carried out on 4, which showed the lowest transition temperature and thus should feature the highest T[LIESST]. It was found that the relaxation process for the photo-induced high-spin state is complex and occurs in two or three steps at around 80 K, which places it on the T\(_0\) = 120 K line of the T[LIESST] vs. T\(_{1/2}\) database proposed by Létard et al.\(^6,26\)

Currently we are working on further studies to vary the ligand and come to an understanding of the LIESST properties of these kinds of complexes.

## Experimental section

### General procedures

All reactions were carried out under an argon inert gas atmosphere using standard Schlenk and cannula techniques. NMR spectra were recorded on a Bruker Avance III 500 spectrometer; chemical shifts for \(^1\)H and \(^{13}\)C are referenced internally to the residual protons and to the \(^{13}\)C-NMR signal for the deuterated solvent. Elemental analyses were performed using a Thermo FlashEA 1112 analyzer. Mass spectra were recorded on a Bruker micrOTOF-QIIa mass spectrometer operating in ESI mode. Magnetic susceptibility data for 4 and 5 were collected using a Quantum Design MPMS-XL5 SQUID magnetometer under an applied field of 0.2 T over the temperature range 10–300 K in the settle mode at a cooling/warming speed of 10 K min\(^{-1}\), measuring the magnetization every 5 K, after the temperature was settled within a 0.5 K accuracy for 10 seconds. All samples were placed in gelatin capsules held within plastic straws. Samples for magnetic and photomagnetic

measurements were prepared by crystallization in an analogous manner to the preparation of single crystals. Identity of the structure and that no solvent molecules were incorporated in the lattice was checked by PXRD. The data were corrected for the diamagnetic magnetization of the ligands, which were estimated using tabulated Pascal’s constants and of the sample holder. Photomagnetic measurements for 4 were performed using a Spectra Physics Series 2025 Kr⁺ laser (514.5 or 647 nm) or an 830 nm photodiode, coupled by means of an optical fibre to the cavity of an MPMS-5S Quantum Design SQUID magnetometer. The optical power at the sample surface was adjusted to prevent warming of the sample. After being slowly cooled at 10 K the sample in the low-spin state was irradiated and the change in magnetic susceptibility was followed. When the saturation point was reached the laser was switched off and the temperature increased at a rate of ≈0.3 K min⁻¹. The magnetization was measured every 1 K. T(FLIESST) was determined from the minimum of a dχ/dT vs. T plot for the relaxation process. Temperature dependent susceptibility measurements in solution were performed using a Norell N15CCI-B coaxial insert set. A defined amount of complex was weighted in an NMR tube. This NMR tube was transferred into a Schlenk tube and filled with argon. To this tube a weighted amount of a solution of aceanaphthene in d₄-acetonitrile was added. The tube was sealed with a plastic cap in an argon stream, shaken briefly to dissolve the sample completely and then opened in argon stream to insert the inset tube, containing the same solution of aceanaphthene in d₄-acetonitrile, into the NMR tube. The determined values were corrected for expansion of the solvent by tabulated values and the effect of deuteration by multiplication with M(CD₃CN)/M(CH₃CN) as described elsewhere.⁵⁶

THF and diethyl ether were purified by distillation from sodium/benzophenone ketyl. Ethanol was purified by distillation from magnesium and acetonitrile by distillation from calcium hydride. Biphenylene-2,2’-diamine⁵⁶ was synthesized by following published procedures. All other chemicals were purchased by commercial suppliers and were used without further purification.

Synthesis of 2-bromo-6-(1H-pyrazol-1-yl)pyridine (1). This reaction was carried out similarly to the literature procedure.¹¹ 1H-pyrazol (3.02 g, 44.36 mmol) and 2,6-dibromopyridine (10.51 g, 44.36 mmol) were suspended in 20 mL dry dioxane under an argon atmosphere, KO’Bu (4.98 g, 44.36 mmol) was added and the mixture was stirred for 1 h at 100 °C for 48 h. The solvent was then removed in vacuo, water (20 mL) was added and the precipitate was filtered and washed with water (20 mL). The solid was then dissolved in tetrahydrofuran (20 mL) and ZnCl₂-nH₂O (2 g, ca. 11.8 mmol) was added which resulted in the precipitation of an off-white solid. This precipitate consists of the zinc chloride complex of the side product 2,6-bis(1H-pyrazol-1-yl)pyridine and of the zinc chloride complex of the desired product. The mixture was then filtered and the filtrate, which contains the main amount of the desired product and unreacted 2,6-dibromopyridine, was then again treated with ZnCl₂-nH₂O (10 g, ca. 59 mmol). This yielded in a further precipitate, which was collected by centrifugation and washed with ether. The precipitate, namely the zinc chloride complex of the desired product, was dissolved in 25% NH₄(aq) and CH₃Cl₂, the organic phase was separated, the aqueous phase was extracted with CH₃Cl₂ and the combined organic phases were dried over MgSO₄ and then the solvent was reduced in vacuo to yield 2-bromo-6-(1H-pyrazol-1-yl)pyridine (5.97 g, 26.65 mmol, 60%) as a white solid.

¹¹H NMR (500 MHz, CDCl₃): δ (ppm) 6.46 (dd, J = 2.6, 1.7 Hz, 1H), 7.34 (dd, J = 7.7, 0.6 Hz, 1H), 7.64 (t, J = 7.9 Hz, 1H), 7.73 (d, J = 1.1 Hz, 1H), 7.92 (dd, J = 8.1, 0.6 Hz, 1H), 8.52 (dd, J = 2.6, 0.5 Hz, 1H).

Synthesis of 2-(1H-pyrazol-1-yl)pyridine-6-carbaldehyde (2). 2-Bromo-6-(1H-pyrazol-1-yl)pyridine (1 g, 4.46 mmol) was dissolved in dry diethyl ether (20 mL) under an argon atmosphere, cooled to −80 °C and then BuLi (2.5 M in hexanes, 1.8 mL, 4.5 mmol) was added dropwise. The reaction mixture was stirred at −80 °C for 10 min, whereas the color of the suspension changed from yellow to orange. Then N,N-dimethylformamide (DMF, 0.35 mL, 4.5 mmol) was added and the mixture was stirred for a further 10 min while the temperature elevated to −60 °C. To this orange solution hydrochloric acid (37%, 0.5 mL, 6 mmol) was added and the temperature was allowed to rise to room temperature. The reaction mixture was neutralized with NaHCO₃, H₂O (25 mL) was added and the product was extracted with diethyl ether (1 × 20 mL) and dichloromethane (1 × 20 mL). The organic phases were collected, dried over MgSO₄ and the volatiles were removed in vacuo to give 2 (780 mg, 4.39 mmol, 98.3%) as pale yellow plates.
Synthesis of [Fe(bpy)]_3ClO_4 (4). The secondary amine 3 (106.5 mg, 0.214 mmol) and [Fe(H_2O)_6][BF_4]_2 (72 mg, 0.214 mmol) were stirred under an argon atmosphere in dry CH_2Cl_2 (5 mL) for 3 h. Then dry Et_2O (10 mL) was added dropwise to give a greenish precipitate, which was centrifuged and washed with more diethyl ether (5 mL). The green powder was dried in vacuo to give complex 4 (120.7 mg, 0.166 mmol, 77.6%).

H NMR (500 MHz, CDCl_3): δ (ppm) -70.05 (2H), -17.87 (2H), -9.89 (2H), -7.94 (2H), 14.11 (2H), 20.59 (2H), 43.12 (2H), 55.89 (2H), 58.83 (2H), 62.54 (2H), 70.31 (2H), 71.26 (2H), 74.81 (2H). ESI-TOF HRMS: 641.1663 (M-BF_4, calc. 641.1659); 553.1567 (M-2BF_4H, calc. 553.1546); 277.0835 (M-2BF_4, calc. 277.0810). μ_Ret (25 °C, Evans' method): 4.86 μ_R. Anal. calcd (%) for C_{30}H_{36}ClFeNO_8 (753.33 g mol⁻¹): C 49.49, H 3.60, N 15.39. Found C 48.34, H 3.70, N 15.19.

Synthesis of [Fe(bpy)]_3ClO_4 (5). The secondary amine 3 (98.6 mg, 0.198 mmol) and [Fe(H_2O)_6][ClO_4]_2 (71.8 mg, 0.198 mmol) were stirred under an argon atmosphere in 4 mL 1:1 CH_2Cl_2–CH_2Cl_2 (v/v) for 3 h. Then dry Et_2O (10 mL) was added dropwise to give a greenish precipitate, which was centrifuged and washed with more diethyl ether (5 mL). The green powder was dried in vacuo to give complex 5 (95.8 mg, 0.127 mmol, 64.3%).

H NMR (500 MHz, CDCl_3): δ (ppm) -70.05 (2H), -17.87 (2H), -9.89 (2H), -7.94 (2H), 14.11 (2H), 20.59 (2H), 43.12 (2H), 55.89 (2H), 58.83 (2H), 62.54 (2H), 70.31 (2H), 71.26 (2H), 74.81 (2H). μ_Ret (25 °C, Evans' method): 4.92 μ_R. Anal. calcd (%) for C_{40}H_{44}ClFeNO_8 (753.33 g mol⁻¹): C 47.83, H 3.48, N 14.87. Found C 47.67, H 3.44, N 14.75.

Synthesis of [Zn(bpy)]_3ClO_4 (6). The secondary amine 3 (103.4 mg, 0.207 mmol) and [Zn(H_2O)_6][BF_4]_2 (72 mg, 0.207 mmol) were stirred under an argon atmosphere in dry CH_2Cl_2 (5 mL) for 3 h. Then dry Et_2O (15 mL) was added dropwise to give a pale yellow precipitate, which was centrifuged and washed with more diethyl ether (5 mL). The product was dried in vacuo to give complex 6 (135.3 mg, 0.183 mmol, 88.5%).

H NMR (500 MHz, CDCl_3): δ (ppm) 3.85 (dd, J = 18.5 Hz, 2H, CH_2), 4.43 (dd, J = 18.8, 9.5 Hz, 2H, CH_3), 5.31 (dd, J = 9.5, 5.5 Hz, 2H, NH), 6.47 (dd, J = 8.0, 0.9 Hz, 2H), 6.84 (dd, J = 2.8, 2.0 Hz, 2H), 6.92 (td, J = 7.8, 1.6 Hz, 2H), 6.97 (dd, J = 7.8, 0.5 Hz, 2H), 7.15 (td, J = 7.5, 1.1 Hz, 2H), 7.31 (dd, J = 7.6, 1.5 Hz, 2H), 7.80 (d, J = 1.9 Hz, 2H), 7.9 (m, 2H), 8.10 (t, J = 8.0 Hz, 2H), 8.70 (m, 2H). ESI-TOF HRMS: 649.1680 (M-BF_4, calc. 649.1601), 561.1541 (M-2BF_4H, calc. 561.1488), 281.0807 (M-2BF_4, calc. 281.0780). Anal. calcd (%) for C_{30}H_{36}BF_4N_3Zn (737.57 g mol⁻¹): C 48.66, H 3.89, N 14.65. Found C 48.85, H 3.55, N 15.19.

Acknowledgements

S. H. and H. P. would like to thank the Fonds der Chemischen Industrie for a Liebig-Stipendium and a Doktorandenstipendium. We also want to thank M. Mehring and M. Schlesinger for the XRPD measurements. S. S. and B. W. thank the University of Bayreuth, the Deutsche Forschungsgemeinschaft (WE 3546-1 and SFB 840/A10) and the Fonds der Chemischen Industrie for financial support. G. C. and J.-F. L. would like to thank the GSI-Advanced Materials in Aquitaine (AMA) and the Aquitaine Region for supporting the development of the ICPA (International Center of Photomagnetism in Aquitaine) platform at the ICMCB.
