Title

Benthic foraminifera as bioindicators for assessing reef condition in Kāne‘ohe Bay, O‘ahu, Hawai'i

Abstract

Context

Tropical coral reef environments provide a wide variety of goods and ecosystem services but are experiencing growing pressure from coastal development and tourism. Assessing the status of reef communities along gradients of human pressure is therefore necessary to predict recovery and resilience capacity of reefs.

Aims

Firstly, to determine the overall water quality in Kāne‘ohe Bay, O’ahu, Hawai'i, by employing a low-cost monitoring approach for anthropogenic stress on coral reef areas. Secondly, to assess the suitability of the monitoring approach to complement existing monitoring programs.

Methods

Sediment samples containing benthic foraminifera were used to determine water quality and stressor sources in Kāneʻohe Bay, O’ahu, Hawai'i, by applying the Foram Index (FI) and Bayesian regression analysis. The FI is based on relative abundance of functional groups of larger benthic foraminifera.

Key results

Overall water quality in Kāneʻohe Bay may support active growth and recovery of coral reefs in the northern sector but deteriorates around Kāneʻohe City.

Conclusions

Benthic foraminifera can be used as bio-indicators in Hawaiian reefs, providing an easy and fast-to-apply method for assessing short-term changes in water quality and stress sources. Implementing benthic foraminifera studies within existing long-term monitoring programs of Hawaiian reefs can be beneficial for conservation efforts.

Implications

Within a historic context, our findings illustrate the modest recovery of an ecosystem following pollution control measures but highlight the need of conservation efforts for reef environments adjacent to major human settlements.

Introduction

Coral reef environments provide a wide variety of goods and services, including waste detoxification and vital food resources for millions of people (Holmlund and Hammer 1999; Adger *et al.* 2005; Woodhead *et al.* 2019). However, current climate warming, the increase of ocean pollution, acidification of the oceans, and the manifold forms of habitat destruction endanger modern coral reefs (Pandolfi *et al.* 2003; Barnosky *et al.* 2017). To evaluate and subsequently manage coral reef ecosystems, reefal, ecological, environmental, and anthropogenic characteristics must be considered (Sandin *et al.* 2008). Anthropogenic impacts in particular are a growing threat to coral environments, as the population of the Earth is projected to increase dramatically in the next 35 years (Dubois, 2011). Coral reef environments on the Hawaiian Archipelago represent one of the most intensively studied reef systems worldwide, with an exceptional record of both natural and human-induced perturbations of the past. Coral reef ecosystems on Hawai'i experienced major bleaching events (Burke *et al.* 2011) as well as rapid sea level rise (Leuliette 2012) and were subject of major anthropogenic impacts (Williams *et al.* 2008; Filous *et al.* 2017; Friedlander *et al.* 2018). Anthropogenic stressors on Hawai'i likely have amplified in the last decades, as coastal development continues to increase with a growing human population. Current long-term monitoring programs focus mainly on the description of spatial and temporal dynamics of Hawaiian reef communities, and less on the potential anthropogenic drivers of these dynamics (Jokiel *et al.* 2004; Rodgers *et al.* 2015).

Here we employ a low-cost approach to monitor anthropogenic stress on coral reef areas on Hawai'i and assess its suitability to complement existing monitoring programs. The methodological approach was initially developed for western Atlantic-Caribbean reefs (Hallock *et al.* 2003) but has since been successfully extended to reefal areas all over the world (Hallock 2012). We first report the abundance and distribution of benthic foraminifera genera from 13 sediment samples in Kāne‘ohe Bay, Hawai'i. As assemblages of benthic foraminiferal shells in sediment closely reflect water and sediment quality, they can be used to monitor high-resolution records of coastal pollution (Hallock *et al.* 2003; Frontalini and Coccioni 2008; Uthicke and Nobes 2008) and anthropogenic stress (Alve 1991; Frontalini and Coccioni 2008; Caruso *et al.* 2011; Shabbar 2016). To do so, we transformed the raw abundance counts of foraminiferal shells into a well-established measure for water quality, the Foram Index (FI) (Hallock *et al.* 2003; Hallock 2012; Prazeres *et al.* 2020). The FI is based on the ratio of three functional groups of foraminifera, which include taxa of larger foraminifera that host algal symbionts and reflect high water quality, pollution-tolerant opportunistic foraminifera that dominate high-stress environments, and small taxa that proliferate in response to nutrification. We then used the FI and distances to potential centers of anthropogenic stress (Kāneʻohe City, Kahaluʻu City, and the Marine Corps Base Hawai'i) to analyze whether spatial assemblage shifts are correlated with anthropogenic impacts in Kāneʻohe Bay. Our results indicate that overall water quality is high in Kāneʻohe Bay but deteriorates around Kāneʻohe City. Given the potential applicability and a low expenditure of foraminiferal-based measures for water quality, we propose that implementing benthic foraminifera as bio-indicators for Hawaiian reefs can be beneficial for existing long-term monitoring programs.

Materials and methods

Regional setting

Kāneʻohe Bay, situated on the windward coast of Oʻahu, Hawai'i, is one of the most intensely studied estuarine and coral reef systems in the world (Bathen 1968; Banner 1974; Hunter and Evans 1995). It is located on the northeast coast of Oʻahu with a length of 13.5 km at its maximum and 4.5 km width from shore to the outer barrier reef (Fig. 1). The bay is bordered by the only barrier reef in the Hawaiian archipelago. The reef is cut by two natural channels and a dredged ship channel connecting the north and the south passages. Between the 1940's and 1970's, Kāne'ohe Bay coral reefs suffered impacts to the reef community due to anthropogenic activities concomitant with land use changes, such as eutrophic conditions ensuing from sewage discharges into the bay, and channelization of streams (Pastorok and Bilyard 1985; Ringuet and Mackenzie 2005). Additionally, extensive reef dredging amplified these impacts. Two large sewage outfalls were diverted from the bay in 1977-1978 (Smith *et al.* 1981; Laws and Redalje 1982), followed by a partial recovery of coral-reef dominated communities in Kāne'ohe Bay (Hunter and Evans 1995). This trend, however, was slowing down since 1984 and subsequently even reversed, co-occurring with increasing size of the adjacent cities Kāne'ohe and Kahalu'u and the expansion of the marine corps-base (Hunter and Evans 1995). This urban growth concurred with non-point source pollution as well as increased runoff nutrient input into the bay linked to considerable impacts on the bay ecosystem (Ringuet and Mackenzie 2005; Hoover *et al.* 2006). Foraminiferal assemblages responded to these perturbations with a shift in composition and a severe decrease in abundance (Hallock, personal communication). Kāne'ohe Bay is monitored since 1999 as part of the Hawai'i Coral Reef Assessment and Monitoring Program (CRAMP). Between 1999 and 2002, coral reef coverage decreased in five out of six sampled stations in Kāne'ohe Bay (Jokiel *et al.* 2004), whereas only one of the six stations showed a decrease over a 14 yr period (Rodgers *et al.* 2015).

Sampling sites

Samples were collected during 2017 from Kāne'ohe Bay by researchers from the Florida Museum of Natural History sampling surface sediment by scuba diving. Thirteen samples were taken across a variety of shallow water environments between one and fourteen meters water depth and a variety of distances from settlements on the island to examine the spatial variation in assemblage and any potential impact from anthropogenic sources (Suppl. Table 1). The locality in the bay, the longitude and latitude, the water depth, and the habitat were assigned to each individual sample. The distance to centers of anthropogenic stress (cities and military bases) were calculated by using the program Google Earth (http://earth.google.com).

Sampling treatment

The foraminiferal assemblages were wet sieved through 63 μm and dried in a low temperature oven (~40 °C). Following this, up to 200 foraminiferal specimens of each sample were picked under a stereo microscope following a standard protocol (Hallock *et al.* 2003). Each sample was split into smaller subsets of approximately 0.1 g and weighed. We then used the first weighed subset of the sample to pick out foraminiferal specimen until we reached a number of 200 specimen (Dix 2002). If less than 200 specimen were present in the subset, we repeated the picking procedure on a second 0.1 g subset from the sample. This procedure was repeated until 200 specimens were obtained or until the entire gram of sample was processed. Foraminiferal taxa were identified to generic level according to Loeblich Jr and Tappan (2015). We used the Foram Index (FI) (Hallock *et al.* 2003; Hallock 2012; Prazeres *et al.* 2020) to asses water quality and suitability for reef-building corals of the study area. The FI is defined by the ratio of large benthic foraminifera which host phototrophic endosymbionts to small heterotrophic foraminifera. Heterotrophic taxa proliferate under the input of nutrients into the sea water, while large symbiont-bearing taxa are constrained to water-quality conditions similar to those required by corals. Under extreme local nutrient input, with subsequent intermittent anoxia in the sediments, a few known taxa of heterotrophic, stress-tolerant foraminifera can become dominant (Alve and Bernhard 1995; Carnahan *et al.* 2009; Pisapia *et al.* 2017). Accordingly, we classified specimens into one of three functional groups: symbiont-bearing, opportunistic, or other smaller taxa. For each sample, the FI was determined by the equation: $FI = (10 \times P_s) + (P_o) + (2 \times P_h)$, where “P” is the proportion and where subscript “s” represents symbiont-bearing foraminifera, subscript “o” represents opportunistic foraminifera, and subscript “h” represents other small, heterotrophic foraminifera. The FI scale ranges from 1 to 10, with FI > 4 indicating environment conducive to reef growth, 2 < FI < 4 indicating environment marginal for reef growth and unsuitable for recovery, and FI < 2 indicating stressed conditions unsuitable for reef growth. During specimen counting, the degree of bioclast preservation was also evaluated (Carnahan *et al.* 2009; Hallock 2012). Badly broken or possibly reworked specimen, which could not be identified to genus level, were omitted from the analysis (Hallock *et al.* 2003; Prazeres *et al.* 2020). Relative abundance (proportions of the subsample) and absolute abundance (numbers of specimens per gram of sediment) where calculated following standard procedures (Hallock *et al.* 2003).

Data analysis

All analysis were carried out using the R programming environment (R Core Team 2021). We used the ‘tidyverse’ package collection for data wrangling and visualization (Wickham *et al.* 2019), the ‘vegan’ package (Oksanen *et al.* 2020) for non-metric multidimensional scaling ordination (nMDS), and the ‘brms’ package for Bayesian regression analysis (Bürkner 2017). nMDS was conducted to analyze the community structure of all samples and was based on Bray-Curtis dissimilarity. Bayesian linear regression analysis was carried out to test if the water quality as indicated by the FI in the southern area of Kāneʻohe Bay, which is mainly characterized by urban development, is lower compared to the northern sector, which is further away from cities and military bases. We first fitted three regression models with the FI as the outcome variable including an intercept only null model, a model with distances to all major human settlements in the bay (Kāneʻohe City, Kahaluʻu City, and MCBH), and a model with a all settlements and additionally water depth as a predictor variable. This approach enabled us to compare the predictive effect of distance to human settlements to a null baseline as well as to water depth, which might be a possible confounding driver of the FI (Hallock 2012). Models were compared by means of leave-one-out cross-validation using Pareto-smoothed importance sampling (Vehtari *et al.* 2017). We transformed the outcome and all predictor variables to z-scores prior to model fitting to facilitate an easier calculation of the joint posterior probability distribution. All three models were fitted via the probabilistic programming language Stan using a Hamiltonian Monte Carlo Markov Chain (MCMC) and the No-U-Turn sampler (Gelman *et al.* 2015). We used weakly informative priors for all parameters which were easily exceeded by the actual data while reducing over-fitting compared to traditional frequentist approaches. The joint posterior probability distribution was estimated by four MCMC chains, a warm-up of 500 samples, and 2000 actual samples. We then used standard convergence and efficiency diagnostics to evaluate the sampling performance, based on Rhat values and the number of effective sample size (Vehtari *et al.* 2019).

Robustness testing

As a FI value of 10 is possible but unusual even in pristine regions (see discussion), we further conducted a robustness test by removing all samples with values above 9.5 and repeating our analysis on this data subset. We then compared the results from the analysis based on the subset to the results based on all samples, to see whether potentially biased samples with FI values above 9.5 might confound our findings.

Results

Community analysis

The assemblages show an average generic level-richness compared to other tropical warm-water coral reefs (Hallock 2012). In total, 15 genera were identified and classified according to the three functional groups: symbiont-bearing, opportunistic, and small heterotrophic foraminifera (Table 1). A clear spatial distribution of foraminiferal assemblages Kāneʻohe Bay can be perceived: The northern sector is dominated by symbiont-bearing genera, in the middle sector all three functional groups are present, and the southern sector is characterized by heterotrophic genera (Fig. 1). Sample sites located on the barrier reef (1- 6) are all dominated by symbiont-bearing foraminifera. In the middle sector of the bay, between the barrier reef and the coastline, the number of small heterotrophic genera increases. While the four samples which are located closest to the shore (9, 11, 12, 13) are dominated by small heterotrophic genera, the three samples in the middle sector (7, 8, 10) show an equal distribution between heterotrophic and symbiont-bearing taxa. Opportunistic genera are most abundant in the middle sector; however, they still remain the least abundant of the three functional groups even in the middle sector. Symbiont-bearing and opportunistic taxa are less abundant in the four near-shore samples. Overall, absolute abundance ranged from 0.9 to 133.3 individuals per gram of sediment, including three samples with less than 2 specimen per gram of sediment. The most abundant genera of the symbiont-bearing functional group were *Amphistegina* spp., *Peneroplis* spp., *Sorites* spp., and *Heterostegina* spp. (see Supplementary Information Table 1 for relative and absolute abundance of all foraminiferal taxa). Opportunistic species were generally rare, and included *Ammonia* spp., *Elphidium* spp., and *Bolivinida* spp. The genus *Amphistegina* spp. from the symbiont bearing group had the greatest relative abundance. It dominated 46% of the assemblages, whereas the other 54% were dominated by small heterotrophic group genera. *Amphistegina* spp. also constituted 38% of the total foraminiferal population in Kāneʻohe Bay and was present in 7 of the 13 sampling stations. However, *Peneroplis* spp. and *Sorites* spp. were found in 11 of the 13 sampling stations, making them the most widespread genera. Non-metric multidimensional scaling based on the foraminiferal assemblages show a clear clustering of the samples in three groups, closely corresponding to the three functional groups used to calculate the FI (Supp. Fig. 3).

Foram Index

The FI calculated for the sampled sites revealed values between 2.1 and 10, with a median of 6.8 (Suppl. Fig. 1, Suppl. Table 2). Four samples (9, 11, 12, 13, located close to the shore) are indicating environment marginal for reef growth and unsuitable for recovery, whereas the remaining nine samples are indicating environment conducive to reef growth. FI results mirror assemblage clusters attained by applying a non-metric multidimensional (nMDS) scaling approach to the samples, indicating a strong biotic driver for foraminiferal distribution and emphasizing the reliability of the FI.

Distance to human settlements

Model comparison showed that distance to human settlements (Kāneʻohe City, Kahaluʻu City, and Marine Corps Base Hawai'i (MCBH)) is a robust predictor of the FI (Suppl. Table 3). The Bayesian regression model revealed a substantial relationship between FI values and distance to Kāneʻohe City, showing that samples scored lower FI values when they were located closer to Kāneʻohe City (Fig. 2 and Fig. 3). The model yielded no robust relationships between FI values and distance to Kahaluʻu City and MCBH respectively. A regression model fitted on a subset of the data for robustness testing (see methods section and Suppl. Fig. 2) yielded similar results, with a strong relationship between the FI and distance to Kāneʻohe City while showing no consistent relationship for distance to Kahaluʻu City and to the MCBH. Our results hence indicate that a stress gradient is present in Kāneʻohe Bay, with the highest stress close to Kāneʻohe City and less further away from Kāneʻohe City, while smaller settlements in the bay have less to no impact.

Discussion

Using a foraminiferal-based index for water quality, we found a clear spatial stress gradient in Kāneʻohe Bay with good water quality in the outer bay and low water quality close to the shore. The distance of each sediment sample to Kāneʻohe City turned out to be a strong predictor of this trend, while smaller settlements in the bay seemed to be less influential. This effect might result from non-point pollution by the adjacent city of Kāneʻohe, or by organic matter input through the river mouths in this area. Our results are in line with other empirical studies showing periodical reef degradation in Kāneʻohe Bay either through anthropogenic activities or natural processes such as freshwater flooding and erosional runoff (Banner 1974; Hunter and Evans 1995; Laws and Allen 1996; Jokiel and Brown 2004; Neilson 2014). We further found the majority of the sampled area conducive to reef growth. One reason for these moderate to good conditions for coral reefs could be that the water-body of Kāneʻohe Bay is relatively well mixed vertically and horizontally under most conditions (Ringuet and Mackenzie 2005). Possible pollution sources around Kāneʻohe are therefore quickly dispersed, as well as organic matter from riverine input. However, one third of our samples indicated environment marginal for reef growth and unsuitable for recovery. This might be particularly warning as major coral bleaching events were observed in Kāneʻohe Bay in the past (Jokiel and Brown 2004; Neilson 2014). Reefs close to the shore and especially close to Kāneʻohe City might hence not be able to recover after a period of perturbations, be it natural or anthropogenic stressors. We therefore agree with other current reef health assessments of the Bay that it is necessary to pay continuous attention to local pollution, impacts of climate change, sedimentation, and harvest issues (Jokiel *et al.* 2004; Bahr *et al.* 2015; Rodgers *et al.* 2015). Ongoing monitoring programs in the bay could benefit from the implementation of the Foram Index as a fast and low expenditure method to assess conditions for reef growth. Although this index was not specifically developed for use in islands in the central Pacific Ocean (Hallock *et al.* 2003), our study shows that the application to Hawaiian reefs is feasible as our results are in line with other studies in Kāneʻohe Bay using a variety of indicators for reef health and water quality (Maragos 1972; Hunter and Evans 1995; Fagan and Mackenzie 2007; Rodgers *et al.* 2015; Friedlander *et al.* 2018).

The Foram Index values obtained in this study appear similar to those from other regions with anthropogenic pollution (Barbosa *et al.* 2009; Carnahan *et al.* 2009; Caruso *et al.* 2011; Barbosa *et al.* 2012). However, FI values of 10 are seldom recorded in other studies even in pristine regions (Barbosa *et al.* 2009; Barbosa *et al.* 2012). In this study, 5 samples (1, 2, 3, 5, 6) recorded a FI value of approximately 10 in the outer bay of Kāne‘ohe, mainly consisting of lens-shaped *Amphistegina* spp. and *Heterostegina* spp. These genera tend to remain in the sediment for a prolonged time due to their test-shape and their robust nature. Samples with a FI of 10 may hence have experienced reworking by currents for a longer time interval and could be therefore biased. However, these potentially biased samples don’t confound our findings, as the robustness testing based on samples 6 to 13 showed equal results compared to the analysis of all samples. All other samples showed good preservation of delicate test-forms, indicating that the FI from these samples can be considered as reliable and represent accumulation over short time. Northeasterly winds present in the northern area (Smith *et al.* 1981; Laws and Allen 1996) might have removed smaller foraminifera taxa from the sediment by grain size sorting, resulting in biased high FI values for this area. Winter storm motion and trade wind influence, however, is restricted to the northern area (Bathen 1968) and should not influence samples from the southern area. Although the FI can vary with other parameters such as sediment texture (Narayan and Pandolfi 2010), hydrodynamic regime, and light penetration (Barbosa *et al.* 2009), various studies have shown that the FI is primarily related to water quality (Uthicke and Nobes 2008; Koukousioura *et al.* 2011; Velásquez *et al.* 2011; Reymond *et al.* 2012; Oliver *et al.* 2014). The results from our Bayesian regression framework might support this, as there was no apparent relationship between the FI and water depth (Suppl. Table 3). Hence, high FI values of samples 1 to 5 could be biased by reworking and/ or hydrodynamic sorting, but we expect remaining samples to be robust and reflect true water quality. Based on these, the coastal waters adjacent to Kāne‘ohe City in the southern sector seem to be impacted by anthropogenic stress and/or organic material input with eutrophic water conditions.

We emphasize, based on our results, that implementing benthic foraminifera studies within existing long-term monitoring programs of Hawaiian reefs can be beneficial for conservation efforts. We showed that benthic foraminifera can be used as bio-indicators in Hawaiian reefs, providing an easy and fast-to-apply method for assessing short-term changes in water quality and stress sources. Abundance and distribution of benthic foraminiferal taxa reported in this study can hence be used as a baseline to compare changes in Kāne‘ohe Bay over both time and space. In conclusion, we found a clear and robust spatial pattern for reef suitability in Kāne‘ohe Bay, with areas closer to the shore and especially closer to Kāne‘ohe City being less suitable, while samples from the northern bay area indicated conditions more suitable for reef growth and recovery. Our findings highlight the need of an ongoing monitoring for reef areas in Kāne‘ohe Bay to protect the frail local ecosystem from both natural and anthropogenic impacts.
